ABSTRACT

Labour Market Policy and the Equity-Efficiency Trade-Off[*]

This paper studies labour market policy in a society where differently gifted individuals can invest in training to further increase their labour market productivity. Furthermore, the government seeks both efficiency and equity. Frictions in the matching process create unemployment and differently skilled workers face different unemployment risks. We show that in such an environment, training programmes targeted to the disadvantaged workers complement passive transfers (UI benefits), unlike a general training subsidy. Combining passive subsidies with a training subsidy conditioned on individual unemployment duration – the typical Active Labour Market Programme – implies a favorable trade-off between equity and efficiency which encourages relative high spending on training.

1 Introduction

Active labor market policy was adopted by most advanced countries over the 1990s. The announced intension behind this policy is to protect workers that are exposed to negative employment chocks due to changing market conditions. The ambitions are to reduce the skill loss during extended unemployment periods and to redirect the skills of those that are left idle by new technology or increased international trade. The countries differ with respect to the emphasis they put on the active programs but they share the fact of having very limited success with the programs in terms of increasing the employment prospects of program participants relative to non-activated unemployed workers. This is surveyed by Martin (2000) Heckman, Lalonde, Smith (1999) and OECD (2003).

Despite this discouragement, the countries continue with the active programs. This could simply be policy failure. Alternatively, the governments might have other objectives for the programs: the governments might in fact look at the active policy as education that increases the productivity of disadvantaged workers but at the same time acknowledged that increasing equity through this policy comes at some costs in terms of reduced efficiency. Even if there are no effects at the mean for any of the programmes, there could be an effect at the macro level - e.g., less inequality - if it is the more disadvantaged workers who gain productivity from the programmes. This is conceivable as Martin (2000), Heckman, Lalonde, and Smith (1999) and OECD (2004) also conclude that some programmes have significant effects for some groups of individuals. In OECD (2003) it is also suggested that activation policies have reduced poverty rates in some European countries.

We claim that the general picture of active labor market policy (ALMP) and its effects are not well understood. Positive individual post-program effects are certainly too narrow an objective to measure the effectiveness of ALMP on. And both the macro effects via the wage setting and/or on the income distribution, and the individual screening effects needs to be carefully assessed empirically before we can assess the general costs and benefits of these programs.

This paper studies the impact of different social preferences on the optimal characteristics of labor market policy. It develops a competitive search equilibrium model[1] with a government that pursues a combined goal of maximizing efficiency and equity. Firms make irreversable investments in vacancies. Workers are paid wages and choose to invest in skills. In this environment, the optimal labor policy addresses the social concern that some workers have less ability to use and aquire the skills needed by employers.

---

[1]In line with the model of competitive labour auctions with coordination frictions (Julien, Kennes and King 2000, Shimer 2001).

The focus of our policy analysis is the following questions: are active programs complements to passive programs, and if so what is the best active complement to a passive UI benefit scheme, an education subsidy scheme for all or a training subsidy targeted at the least able workers and further, should it be duration dependent. These questions, in particular the one concerning the timing of the subsidy, have not been addressed by the fast advancing literature on how to organize unemployment policy (time-varying policy in our terminology).[2]

We find that our model can explain the main featues of labor policy across OECD countries. In particular, our model explains why some countries spend signifigant resources on both active and passive labor programs while others do not. Consistent with this observation is the fact that high spending countries appear to have better records on income redistribution than low spending countries. Moreover, we are able to replicate these features about labor policy even though we assume risk neutral agents and a competitive search equilibrium. Therefore, neither borrowing constraints nor wage inefficiencies are important to establishing our results. And in contrast to the economics of education literature we focus on a governments (possibly) equity concerns as what drives the policy conclusion. For instance, there are no externalities in our model to make training subsidies optimal from an efficiency point of view. But there could be an equity motivated case for a training subsidy in situations where the advantaged workers face little unemployment and the disadvantaged workers face high unemployment.

The paper is organized as follows. In section 2, we present some background factors and motivates the issues taken up in this paper. In section 3 we introduce a simple directed search model with a government that wish to maximize a social welfare function using a number of policy instruments. In section 4, we solve the equilibrium of the model with general versus targeted training, whereas Section 5 is concerned with the equilibrium when training is targeted and in addition time-varying and in Section 6 we offer some concluding remarks.

2   Background and motivation

A stylized fact is about to emerge among the developed countries. Passive and active unemployment programmes seem to be complementary tools to the governments. Passive programmes are traditional unemployment in-

---

[2]This literatur is surveyed in Frederiksen and Holmlund (2003). One of the more complex contributions of this litteratur, to follow along from the seminal paper by Shavell and Weiss (1979), is the recent study by Pavoni and Violante (2004) who characterizes the optimal sequense of different elements of labour market policies along an unemployment spell. Their main conclusion is that the timing of the variours elements - passive as well as active - of a targeted policy is very important for the effectiveness of the overall policy.

surance schemes and active programmes are training activities targeted at
unemployed individuals as opposed to, for instance, a general training or
education subsidy. Active programmes can be education aiming at upgrad-
ing the unemployed workers' skills or employment programmes supposed to
prevent skill loses during periods of unemployment.

Figure 1 illustrates the patterns by which public funds are spent on pas-
sive and active policy programmes among selected OECD countries. Active
and passive policy seem to be complements. The apparent complementary
pattern is also found following a particular country over time. In this case
major reforms are visible as structural shifts. In fact, it is hard to find exam-
ples of countries to whom the picture suggests that the two policy measures
are substitutes rather than complements.

Figure 1: Active and passive labour market policy as percentages of GDP
for OECD countries

Active and passive Labour market policy as percentages of GDP for
selected OECD countries for a time period is illustrated in Figure 2. An
apparent complementary pattern, found in Figure 1, is also found follow-
ing a particular country over time. The lines in Figure 2 are simple OLS
Figure 2: Active and passive expenditures as a percentage of GDP, selected OECD countries, 1986-2000

predictions country by country.

For Denmark and the Netherlands, active and passive policy seems to be substitutes, nevertheless. The following figures show that in these cases major reforms are visible as structural shifts. In Denmark in 1994, there was a general shift towards mandatory activation and in general more emphasis was put on active labour market policy relatively to passive policy. This could explain the shift to the right that we see in Figure 3. In the Netherlands there was a major restructuring of the benefit system in 1987. The replacement ratios were lowered from 80 to 70% and eligibility rules were tightened. Again in 1996 the benefit sanction system was further toughened and in 1998 the Netherlands Job-seekers Employment ACT was introduced. During the more stable years in between we do observe a complementary pattern between active and passive policy (see Figure 4) although it is week.

Another feature that has emerged together with the higher emphasis placed on active policy by many advanced countries since the mid 1990s[3],

[3]See the European Commision (2004) and OECD (2003).

5

Figure 3: Active and passive expenditures as a percentage of GDP, Denmark, 1986-2000

Figure 4: Active and passive expenditures as a percentage of GDP, the Netherlands, 1988-1995

is that the high spenders among these seem to operate on a more favorable equity-efficiency trade off than the other countries. We see this by comparing Figure 1 to Figure 5, which suggests the equity-efficiency trade-off for the group of countries considered. Consider for example the three countries which spend relatively most on active and passive Labour market policy, Finland, Denmark and Sweden. Those countries are also the countries with the lowest gini-coefficients and still is GDP per capita not significantly lower than for the other OECD countries. On the other hand, the USA, the UK, and Italy are spending relatively little on labour market policy and are also the countries with the most unfavorable trade-off between GDP and equality. France and the Nether Lands are in between the two groups; Canada is doing better and Germany and Spain worse in terms of equity given their spending on labor market policy.

Suppose that the optimal policy for any given weight placed on equity relative to efficiency, reveals complementarity, then the reason for the phenomenon in Figure 5 could be that as long as active and passive policy measures are used in the optimal proportions (and that the active programmes are efficiently organized) then higher spending creates not only higher equity but also a more favorable trade-off between equity and efficiency in the sense that the equality goals are not as expensive to reach as they would otherwise have been. That is, spending on programmes in an optimal way moves you to the right in Figure 5.

In this paper we discuss what features could potentially account for this phenomenon. We consider an economy with two types of workers, disadvantaged and advantaged; and two types of working-life paths; one in the "fast lane" and one doing unskilled jobs. The unskilled jobs require little in terms of ability and skills and the productivity is low. The advanced jobs on the other hand require skills, and the productivity and wage can be high.

The government in this paper has taste for both efficiency and equity and in order to pursue its concerns it considers two policy instruments, UI benefits and training subsidies. These instruments have different effects on the labour market. Unemployment falls if workers are better trained and increases if workers obtain higher unemployment benefits. However, higher benefits reduce inequality. UI benefits are automatically given dispropor-

tionately to low income individuals as they are unemployed the most, and hence, a UI benefit scheme is a way of rewording low income individuals without distorting much the incentives for human capital investments at the top. Also a training subsidy can only reduce inequality if not all workers take it up, which does not happen automatically.

If the governments concern is equity a training subsidy can be optimal only if it is possible to restrict it to the disadvantaged individuals. But as we shall see, there is a limited scope for using self-selection schemes unless mimicking can be made expensive; for instance, by conditioning the subsidy on worker characteristics - directly or indirectly.

This is where active labour market policy comes in. Ability is private information so the conditioning needs to be indirectly and these programmes are indirectly targeted to the disadvantaged workers: participation is conditioned on a certain duration of unemployment prior to programme participation, and disadvantaged workers are the ones most likely to experience long term unemployment.

The optimal combination of UI benefits and targeted time-varying train-

ing subsidies (i) greatly reduces the equity-efficiency trade-off, (ii) increases the complementarity relationship between optimal active and passive policies and increases the use of both for given preferences. The reduction in the equity-efficiency trade-off cannot be achieved by a passive subsidy only and a time-varying active subsidy works better than a non time-varying subsidy as it weakens the incentive compatibility constraint on the active subsidy.

3   The model

The focus of our policy analysis is the following questions: are active programs complements to passive programs, and if so what is the best active complement to a passive UI benefit scheme. In order to focus the policy discussion we assume that all education opportunities which yield a positive private return have been undertaken, and on top of that we consider a labour market that allocates labour efficiently. The content of the skills required changes frequently, however, and in order to continue to be able to perform well in an advanced job your skills have to be adjusted accordingly. Hence, a worker has to re-invest continuously in training in order to maintain a constant productivity distance to unskilled labour. These assumptions are inspired by the way new technology often influences the work situation.[4] The advantaged workers invest in training and their expected private return covers the costs of the investment. They all choose the "fast lane" strategy. Concerning the disadvantaged individuals; if the expected unemployment is high then the private return - the higher wage during the employment spells - is not high enough to cover the training costs incurred. So a subsidy might be called for here. The labour market produces significant wage dispersion; the disadvantaged workers receive much lower wages and face higher unem-

---

[4]New technology changes fast and the complementary skills acquired in order to manage any given technology decade change fast as a consequence. In such an environment, human capital investment is an ongoing concern; re-investments in learning is a necessity in many jobs; also in lower level skilled jobs. In order to keep a job as a computer operator one has to train continuously. If you are only able to operate old versions of soft-ware and equipment even though these are just a few years old, this is almost like you have no professional computer skills at all, which implies that you work as unskilled labour as far as computer jobs are concerned. Staying a head in a good job requires training continuously. So training costs are not something that are incurred once and for all and then you are skilled for the rest of your life. Of course, this problem is of no concern to individuals that abstain altogether from investing in training.

ployment risk than advantaged workers. Therefore, policy is justified if the government is also concerned with equity.

The workforce consists of a total population of N infinitely lived workers. The workers are risk neutral with a subjective rate of time preference equal to β. There are two types of workers, $i \in \{A, D\}$ where type A are advantaged and type D are disadvantaged. A fraction η of the labour force is advantaged and the remaining fraction is disadvantaged.

Workers can choose to train, $h = 1$, or not, $h = 0$. For a worker of type i, let y_h^i denote the productivity during employment where $y_1^i > y_0^i$. Let the cost of training be $c_i - g$ units of output per period, where g is a government subsidy to training. The training decision is modelled as a decision to pursue a career that requires a constant investment in skills (as in any balanced growth path). Therefore, higher productivity is achieved only if the worker pays this cost each period regardless of employment status.

Search and coordination friction. It is associated with frictions to get workers and jobs coordinated. Firms have free entry and open job vacancies with a resource cost k per vacancy. The job vacancies are directed towards specific types of labour, search is directed, and each group of workers, distinguished by type and training investment, are in distinct submarkets with independently determined quantities of vacancies. Matching in each submarket is random. Therefore, if v job vacancies are opened, a job searcher in this submarket is approached by a firm with probability

$$p = 1 - e^{-\phi}, \tag{1}$$

where $\phi = v/s$ is the ratio of v vacancies to s job searchers in the submarket. We assume that all job matches are destroyed with a common exogenous probability, δ.

Wage determination. Let Λ denote the present value of a match between a worker of human capital level h and a job vacancy. This present value is given by

$$\Lambda = \frac{y - (c - g)\, h + \beta\delta(V + \Pi)}{1 - \beta(1 - \delta)}, \tag{2}$$

where V is the present value of a job searcher and Π is the expected profit of an unmatched job. Wages are determined by a simple labour auction

10

market (ref: Julien, Kennes and King 2000)[5]. Thus the present value V of a job searcher is given by

$$V = \max\{V(u) + \lambda(\phi)(\Lambda - V(u)), 0\}, \qquad (3)$$

where $\lambda(\phi) \equiv 1 - e^{-\phi} - \phi e^{-\phi}$ is the probability the worker has multiple offers and $V(u)$ is the value of an unemployed worker. The value V is the 'reserve wage' of each labour auction. The equilibrium present value of a job vacancy is given by

$$\Pi = \max\{-k + e^{-\phi}(\Lambda - V(u)), 0\}, \qquad (4)$$

where the free entry of job vacancies ensures that $\Pi = 0$. A worker that leaves employment by a dislocation shock is a job searcher next period. The value of such a worker is given by

$$V(u) = \max\{a - (c - g)h + \beta V, 0\}, \qquad (5)$$

where a denotes unemployment insurance benefits.

All workers can choose to either train or not. The worker's choice of human capital maximizes the return to a worker that enters the workforce unemployed. Thus

$$h = \begin{cases} 1 & V|_{h=1} \geq V|_{h=0} \\ 0 & \text{otherwise} \end{cases}. \qquad (6)$$

The values $V|_{h=1}$ and $V|_{h=0}$ are each determined by equation (6) for the appropriate value of h.

The government's problem. Let W_A and W_D denote the average per period income of advantaged and disadvantaged workers, respectively. Social welfare is determined by a social welfare function, which takes as its arguments, W_A, W_D and η. It is convenient to assume that this social welfare function has the following functional form:

$$Y = \gamma(\eta W_A + (1 - \eta)W_D) + (1 - \gamma)\min\{W_A, W_D\}, \ 0 \leq \gamma \leq 1, \qquad (7)$$

---

[5]Specifically, the auction implies that the entire surplus of a match goes to the firm if the worker is matched with only one firm, and the entire surplus goes to the worker if (s)he is matched with two or more firms. An unmatched agent gets zero.

which is a weighted average of a Benthamite sum of utilities social welfare function and a Rawlsian social welfare function.

The government chooses transfers to unemployed and employed workers to maximize social welfare. In addition to the training subsidy, g, the government gives all unemployed workers an unemployment insurance benefit, a. The unemployment insurance is a passive benefit, because the worker has complete freedom on how it is spent. However, a general training subsidy is an active measure in a sense, because it has to be used on a specific activity, namely human capital investment. Both transfers are paid by a lump sum tax, t. The government balances its budget by setting

$$t = \eta(au_A + hg) + (1 - \eta)(au_D + h'g), \tag{8}$$

where u_A and u_D indicate the unemployment rates of advantaged and disadvantaged workers and h and h' are their respective human capital choices.

3.1 Equilibrium

We can now derive the equilibrium of the model. First we derive the unemployment rate. Consider the gross labour market flows for a group of workers that have market tightness given by ϕ. The fraction of workers employed in a period is given by

$$q_t = z_t + p(\phi)s_t, \tag{9}$$

where z_t is the fraction of all workers that are employed because they did not lose their jobs last period and $p(\phi)s_t$ is the fraction of all workers that are employed because of a successful job search this period. At the end of each period each worker becomes unemployed with probability δ. Thus

$$z_t = (1 - \delta)q_{t-1}. \tag{10}$$

The flows in and out of employment imply that the steady state fraction s workers engaged in job search in each period is given by

$$s = \frac{\delta}{\delta + (1 - \delta)p(\phi_i)}. \tag{11}$$

Job searchers that do not find a job are unemployed. Thus the unemployment rate is given by

$$u = (1 - p)s. \tag{12}$$

Jobs and human capital: the per period income of a worker investing in human capital can be written as follows

$$W_h^i = G_h^i - h(c_i - g) - t, \qquad i \in \{A, D\}, h \in \{0, 1\}, \qquad (13)$$

where G_h^i is the worker's labour market income as a function of their training decision, g is the government's subsidy to training, $h(c_i - g)$ is the cost of training that is born by the worker.

For each type of worker, $i \in \{A, D\}$, the training decision is determined by the difference between the cost of training, $c_i - g$, and the benefit of training, $G_1^i - G_0^i$. Thus the optimal value of h for each group of workers is given by

$$h = \begin{cases} 1 & G_1^i - G_0^i \geq c_i - g. \\ 0 & \text{otherwise} \end{cases} \qquad (14)$$

Given that a competitive search equilibrium model matches jobs and labour constrained efficiently, the equilibrium is simple to derive if we assume that the discount factor approaches unity (see Appendix 2). In particular, for each type of worker, equilibrium market tightness, $\phi_h^i \equiv v_h^i / s_h^i$, is that which maximizes steady state output net of recruiting costs. Thus the workers' labour market income is given by

$$G_h^i = \max_{\phi} \left\{ y_h^i (1 - u_h^i) + a u_h^i - k v_h^i \right\}, i = A, D, \qquad (15)$$

where $u_h^i = e^{-\phi_h^i} s_h^i$ and $s_h^i = \delta / \left(\delta + (1 - \delta)(1 - e^{-\phi_h^i}) \right)$. Firms earn zero profits. Thus all income net of the cost of vacancies goes to workers. In competitive search equilibrium, this income is maximized and the solution is

$$k = \frac{y_h^i - a}{1 - (1 - \delta)(1 - \lambda(\phi_h^{i*}))} e^{-\phi_h^{i*}}, \qquad (16)$$

where $\lambda(\phi) \equiv 1 - e^{-\phi_h^i} - \phi e^{-\phi_h^i}$ is the probability a job searcher gets multiple job offers and where ϕ_h^{i*} is the value of ϕ_h^i that maximizes (15). Hence

Proposition 1 *There exists a unique ϕ_h^{i*} for each y_h^i.*

Proof. ϕ_h^{i*} is positive if $y_h^i - a > k$. Likewise the right-hand side of equation 16 is monotonically decreasing in ϕ_h^{i*} and equal to zero if ϕ_h^{i*} is large. Therefore, there exists a unique equilibrium value of ϕ_h^{i*} for each y_h^i. ∎

Below we will look at optimal policy. First we look at general training programmes, which historically were well established before the more targeted training programmes were introduced with the adaptation of active labour market policy. This happened over the 1990s in many advanced countries and is widespread today. Inspired thereby, we will after having considered optimal general training subsidies allow the government to condition the training subsidy on individual unemployment duration/risks, which is what most active programmes do.

4 Optimal policy with a general versus targeted training subsidy

In this section, we characterize the equilibrium of the model allowing the government a general training subsidy in addition to its passive subsidy (the UI benefits). The problem is solved sequentially. We use the competitive equilibrium allocation of jobs and skills derived above given a set of government transfers. We can then solve for the optimal government transfers while taking the decentralized (optimal) decision rules for jobs and human capital as given.

The government executes the transfers a, g and seeks to maximize the social welfare function

$$Y = \max_{a,g} \gamma(\eta W_h^A + (1-\eta)W_{h'}^D) + (1-\gamma)\min\{W_h^A, W_{h'}^D\} \qquad (17)$$

such that (i) the government budget is balanced with taxes satisfying

$$t = \eta(au_A + hg) + (1-\eta)(au_D + h'g) < S_A, S_D,$$

where h and h' indicate the respective human capital choices of advantaged and disadvantaged workers, (ii) a participation constraint (PC) that all workers prefer participation to benefits (i.e., no voluntary unemployed)

$$W_h^A, W_{h'}^D \geq a \qquad\qquad\qquad (\text{PC})$$

14

and (iii) the determination of W_h^A and $W_{h'}^D$ is given by the equilibrium outcome of the decentralized economy, which is described in section 2.2.

The solution to the government's problem yields the following propositions about optimal labour market policy. Suppose that the government is only interested in wealth maximization, that is $\gamma = 1$. In this case, we have the following result.

Proposition 2 *If social welfare is determined solely by aggregate wealth ($\gamma = 1$), optimal government is laissez faire.*

Proof. Competitive search equilibrium ensures that any subsidy to one group of workers increases their output plus the subsidy an amount less than the cost of the subsidy. ∎

If market tightness and human capital decisions are constrained efficient given the search frictions, a wealth maximizing government never gives subsidies that would distort these optimal decisions. Subsidies are only possible if the government evaluates a unit of income spent by a disadvantaged worker differently than a unit of income spent by an advantaged worker, that is, if $\gamma < 1$. Still, a training subsidy that leads to the adoption of training by both advantaged and disadvantaged workers is not optimal. This is shown by the following proposition.

Proposition 3 *Assume $\gamma < 1$. A rational government never subsidizes the training of both advantaged and disadvantaged workers.*

Proof. If all agents adopt training, the cost of the subsidy is completely born by each group. Therefore, competitive search ensures that the optimal subsidy is zero for both groups of workers. ∎

The direct implication of proposition 2 and 3 is that an optimal training subsidy must always exclude some workers, and it needs to be the advantaged workers that do not get subsidized training as the governments equity concern is the only possible motive for considering training. As we assume that the government cannot condition transfers on a particular workers type, the government will have to relay on self selection.

Suppose that the government seeks to direct the training subsidy to the disadvantaged workers. This objective is met if the following two **incentive**

compatibility constraints (ICC) are obeyed: $W_1^D \geq W_0^D$ and $W_0^A \geq W_1^A$. That is, the disadvantaged workers take up subsidized training while the advantaged workers do not. More explicit, the constraints are,

$$G_1^D - (c_D - g) \geq G_0^D \qquad \text{(ICC(1))}$$

$$G_0^A \geq G_1^A - (c_A - g). \qquad \text{(ICC(2))}$$

The second incentive compatibility constraint implies that the maximum active subsidy to disadvantaged workers is given by

$$g_{\max} = c_A - \left(G_1^A - G_0^A \right). \qquad (18)$$

The behavior of $g_{\max}$ is closely related to the amount spent on passive subsidies as stated by the following proposition

Proposition 4 *The maximum incentive compatible training subsidy for disadvantaged workers, $g_{\max}$, increases as the passive subsidy, a, increases.*

Proof. Comparative statics on equation (15) give $\partial \left(G_1^A - G_0^A \right) / \partial a < 0$

∎

The second ICC defines the minimum subsidy required to make disadvantaged workers train,

$$g_{\min} = c_D - \left(G_1^D - G_0^D \right) \qquad (19)$$

Note that a government will subsidize a training programme only if

$$g_{\min} \leq g_{\max}.$$

This inequality is satisfied only if the marginal increase in labour productivity is greater for disadvantaged workers than advantaged workers.

The preceding results concerning optimal government policy apply to any arbitrary social welfare function in our model. However, in order to derive an exact solution for optimal activation policy, it is convenient to assume (i) the social welfare function is given by equation (7) and (ii) disadvantaged workers are a relatively small fraction of the population. In this case

Proposition 5 *If the government assigns a weight to equity ($\gamma < 1$) and disadvantaged workers are a sufficiently small part of the population (η is close to one), then the constraint optimal training subsidy is $g_{\max}$.*

Proof. If η is large, any training subsidy given by the government that does not lead to training by advantaged workers has virtually no effect on the level of taxation. In this case, the training subsidy can be treated purely as a reduction in training costs for the disadvantaged. This subsidy raises social welfare by an amount bounded away from zero if $\gamma < 1$ with the welfare change of advantaged workers going to zero as η approaching unity. ∎

If disadvantaged workers are a large portion of the population, the optimal training subsidy is not necessarily $g_{\max}$. In this case, the result that the efficiency losses of training are small is not strictly valid. For example, if disadvantaged make up the entire population, proposition 3 establishes that the optimal general training subsidy is zero.

With a heterogenous population there is a case for a policy subsidizing training but it is haltered by the fact that the government cannot discriminated between advantaged and disadvantaged. Although it is possible for the government to sort workers by incentive compatible self-selection schemes, this is still not providing a strong case for a training subsidy. Passive transfers are still the most efficient way of reducing income inequality in this case.

However, the picture changes dramatically if the government can use an extra piece of information like, for instance, the individual workers unemployment risk. Then all of a sudden, training subsidies become an efficient tool in providing equity. As the disadvantaged workers face higher unemployment risk and thus are more likely to experience long-term unemployment, all the information the government needs for implementation is the duration of any unemployed workers current unemployment spell and then condition the training subsidies on the spell length.

There is, however, a complication to the use of unemployment experience as a screening criteria. Under such a policy it becomes an issue for the advantaged workers to try mimicking the disadvantaged workers in order to get subsidized training. When the training subsidy is offered unconditional this is of course not an issue.

The government needs to make sure that advantaged workers do not prefer subsidized training and long unemployment spells rather than no training

subsidy and short unemployment spells. The government does not need to be concerned about the incentives of the disadvantaged workers as they simply cannot get re-employed fast enough to mimic the advantaged workers and neither would they gain anything from conducting such a behaviour.

5 Targeted and time-varying policy

By its nature UI benefits are targeted to the unemployed. The type of active programmes that many countries have implemented are also directed at workers that are unemployed; in particular, at the long-term unemployed workers. In this section we illustrate the difference between a non time-varying subsidy and a time-varying subsidy targeted at the high risk workers in terms of their ability in order to provide equity efficiently. The advantage of time-varying active policy lies in the way its complements passive policy. This complementarity is much weaker for a non time-varying education subsidy.

5.1 Unemployment as a screening device: active unemployment programmes

When we set up the incentive compatibility constraints (ICC) above we did not worry about workers not signalling their true type to the government. This we need to do here for the advantaged workers (the disadvantaged workers cannot mimic the advantaged one). Let $W_h^A(u')$ be the average income to an advantaged worker with training h who has chosen unemployment u'. Now the government needs to make sure that the advantaged workers do not want to be burdened with the unemployment rate of trained disadvantaged workers u_1^D just to get the training subsidy, but rather prefer the unemployment rate of her own type u_0^A, that is, $W_0^A(u_0^A) \geq W_1^A(u_1^D)$. More explicitly, this ICC is $y_0^A(1 - u_0^A) + au_0^A - kv_0^A \geq y_1^A(1 - u_1^D) + au_1^D - kv_1^D - (c_A - g)$, where v_1^D is the equilibrium vacancy in the submarket for trained disadvantaged workers. Recall that $y_0^A(1 - u_0^A) + au_0^A - kv_0^A = G_0^A(u_0^A)$. Thus, written in a form compatible with the ICC's of the previous section, we have,

$$G_0^A(u_0^A) \geq G_1^A(u_1^D) - (c_A - g). \qquad \text{(ICC(2'))}$$

This constraint is more slack than the one needed in the previous section, which was $W_0^A(u_0^A) \geq W_1^A(u_1^A)$). This is so, because $W_1^A(u_1^A) > W_1^A(u_1^D)$, which follows from $u_1^A < u_1^D$ corresponding to $\phi_1^A > \phi_1^D$, as ϕ_h^i increases in productivity. Hence if advantaged workers should mimic disadvantaged workers, this corresponds to that they seem to have a lower productivity and thereby experience a higher unemployment rate as fewer vacancies are supplied.

Before we introduce the new ICC, (ICC(2')), into our model we will make an important simplification in order to facilitate the evaluating of a government training subsidies, which are targeted at workers who have a higher risk of unemployment. Suppose that a is constant and that g_j is given by 0 if individual j is not in a training programme and g if j is being activated, that is, in a training programme. Note that this assumption will make the active transfers dependent on the equilibrium unemployment rate (of course a is linearly dependent since it is only paid in the event of unemployment). We approximate the non-linear relationship between (i) the unemployment rate of a particular type of workers and (ii) the average amount of active training subsidies paid out to such workers by the following simple step-wise function

$$g(u) = \left\{ \begin{array}{ll} g & \text{if} \quad u_i \geq u^* \\ 0 & \text{if} \quad \text{otherwise} \end{array} \right. \tag{20}$$

This is only a crude representation of training subsidy that is conditioned on a sufficient unemployment duration. However, it should capture, to a close approximation, the essential non-linearity between benefit provision and the equilibrium unemployment rate of each group when benefits are determined by unemployment duration.

The per period income of a worker investing in human capital can be written as follows

$$W_h^i = S_h^i - t = G_h^i - h(c_i - g) - t, \qquad i \in \{A, D\}, h \in \{0, 1\} \tag{21}$$

where G_h^i is the worker's labour market income as a function of their training decision, g is the government's subsidy to training, $h(c_i - g)$ is the cost of training that is born by the worker, and t is a lump sum tax determined by the government.

19

5.2 Equilibrium with optimal time-varying policy

The model is unchanged except that the active transfer is paid only if the worker's type observes a sufficiently high unemployment rate. The equilibrium supply of jobs and human capital is approximated by the following static welfare optimization problem. The steady state welfare per worker per period of type $i \in \{A, D\}$ is given by

$$G_i(u^*) = \max_{\substack{h \in \{0,1\} \\ \phi_h^i \geq 0}} \begin{cases} y_h^i(1 - u_h^i) + au_h^i - (c_i - g)h - kv_h^i & \text{if } u_h^i \geq u^* \\ y_h^i(1 - u_h^i) + au_h^i - c_i h - kv_h^i & \text{otherwise} \end{cases} \tag{22}$$

where $\phi_h^i = v_h^i/s_h^i$, $u_h^i = e^{-\phi_h^i} s_h^i$ and $s_h^i = \delta / \left(\delta + (1 - \delta)(1 - e^{-\phi_h^i}) \right)$. Maximizing $G_i(u^*)$ gives

$$\frac{y_h^i - a}{1 - (1 - \delta)(1 - \lambda(\phi_h^{i*}))} e^{-\phi_h^{i*}} = k, \tag{23}$$

which is the same as equation (15). The equilibrium training decision is given by

$$h = \begin{cases} 1 & \text{if } u_1^i \geq u^* \text{ and } G_i(u^*|h = 1) - G_i(h = 0) \geq c_i - g , \\ 0 & \text{if } u_1^i \geq u^* \text{ and } G_i(u^*|h = 1) - G_i(h = 0) < c_i - g , \\ 1 & \text{if } u_1^i < u^* \text{ and } G_i(h = 1) - G_i(h = 0) \geq c_i, \\ 0 & \text{if } u_1^i < u^* \text{ and } G_i(h = 1) - G_i(h = 0) < c_i. \end{cases} \tag{24}$$

Suppose that the government can execute transfers a, g. The government seeks to maximize the social welfare function

$$Y' = \max_{a,g,u^*} \gamma(\eta W_A + (1 - \eta)W_D) + (1 - \gamma) \min\{W_A, W_D\}$$

such that

$$t \equiv \eta(au_A + hg) + (1 - \eta)(au_D + h'g) \leq S_A, S_D$$

is the government's budget constraint. The constraints on this maximization problem are the fact that a, g determine u_A, u_D, h, h' by the equilibrium supply of jobs and human capital in the previous subsection.

Welfare is always higher than in the basic model without time-varying training, because conditioning activation on the unemployment rate gives the government an extra instrument to solve the incentive compatibility problem. In particular, the following policy menu is better.

1. For each value of the passive subsidy, a, compute the equilibrium unemployment rate, u^*, of trained disadvantaged workers.

2. Calculate the payoffs of (i) untrained advantaged workers and (ii) unsubsidized trained advantaged workers when the unemployment rate of advantaged workers is u^*.

3. Set the subsidy of disadvantaged workers equal to the difference of (i) and (ii) in 2.

The reason this scheme outperforms the scheme in the previous section is that the payoff of the unsubsidized constrained trained advantaged workers in 2 is lower than the payoff of unconstrained trained advantaged workers. In particular, for a given passive subsidy, the incentive compatibility constraint of active subsidies is weakened if they are targeted to the long term unemployed. The fact that advantaged workers must mimic the unemployment rate of disadvantaged workers (experience a large duration in unemployment), implies that a larger active subsidy can be paid to disadvantaged workers. Therefore, an incentive compatible training subsidy can be paid to disadvantaged workers even if the training yields significant productivity benefits for advantaged workers, who will otherwise go untrained if training is not subsidized.

In other words, we can show that, ceteris paribus, the impact on the training subsidy, g, from increasing the unemployment insurance, b, is larger in the time-varying case than in the non time-varying case. All proofs are given in the appendix.

Proposition 6 *The impact on the training subsidy, g, from increasing the unemployment insurance, a, is larger in the time-varying case than in the non time-varying case, that is, $\partial g/\partial a|$time-varying case$>\partial g/\partial a|$non time-varying case.*

The effect of these time-varying policies on the relationship between active and passive subsidies is illustrated in the figure below. In the diagram we observe that at low values of the passive subsidy there is only a small gap (the line from point a to b) between the unemployment rates of trained
Figure 6: Unemployment and the passive subsidy

advantaged and disadvantaged workers. In this case, there is only a small additional cost to advantaged workers of accepting the unemployment rate of disadvantaged workers (which is suboptimal from the point of view of advantaged workers) in order to gain the training subsidy. In the diagram, we see that the gap between the two unemployment rates widens as the passive subsidy increases. Therefore, the cost of accepting the unemployment rate of disadvantaged workers is larger. Thus even larger active subsidies can be delivered to disadvantaged workers without violating the incentive compatibility constraint that advantaged workers do not accept the training subsidy.

We have thus illustrated that active and passive subsidies can be strategic complements. The strength of this complementarity is greatly increased if the active subsidy is time-varying. This occurs because higher passive benefits tends to raise the unemployment rate of disadvantaged workers which in turn weakens the incentive compatibility constraint on the active subsidy. And, in contrast to a non time-varying subsidy, a time-varying active subsidy can be delivered optimally to disadvantaged workers even if the marginal gain in productivity (from training) is higher for advantaged workers. Finally, disadvantaged workers must experience a larger gain in

22

productivity if their training is to be subsidized using a non time-varying active subsidy.

The results just presented concludes that time-varying training reduces the trade-off between obtaining efficiency and reducing inequality by raising opportunities for disadvantaged workers.

6   Conclusions

The massive and persistent emphasis put on activation and training of unemployed individuals in developed countries in general and in big-welfare-state countries in particular is a puzzle, because it has been difficult to identify positive effects - individual as well as macro-level effects - from the often huge spending on these programmes. So either politics are irrational or the profession has not been looking for effects in the right places. For instance, even if there are no effects at the mean for any of the programmes, there could be an effect at the macro level - e.g., less inequality - if it is the more disadvantaged workers who gain productivity from the programmes. Suppose income equality is a main objective for some countries along side with high average income. Could it then be that active programmes are favored by some countries because such programmes reduce inequality efficiently when used together with traditional passive programmes like UI benefits? This is the question that we have been discussing in this paper and the answer is in the affirmative. If income equality is a sufficiently strong objective to a government then it might well be rational to implement active training programmes for the long term unemployed together with passive benefit programmes like UI. This combination is far more effective that the combination of UI benefits and a general education subsidy. At the principal level, this could vindicate high spending on activation by countries with strong taste for equity. Our results also suggests that high passive and active spending goes hand in hand. Both these phenomenon can be observed in the data for the OECD countries.

These results are developed in a model with heterogenous workers, human capital investment, and unemployment. The model is "pure" in the sense that 'laissez faire' is efficient: the privately chosen level of training is

efficient and even though disadvantaged workers of low skills are the more unemployed ones, unemployment is efficient and reflects search and matching frictions. There are no externalities to justify training subsidies. We have also deliberately disregarded the traditional insurance aspect of passive policies by letting agents be risk neutral in our model. So it is not the usual missing insurance market that implies government spending on UI in optimum. The redistributive functioning of UI in this model with heterogenous unemployment risk is enough to have passive transfers to unemployed entering the optimal policy packaged (of a government that maximizes a social welfare function that puts weight on both equity and income efficiency).

Furthermore, not only can we explain the joint use of passive and active subsidies, the model also shed light on the big variation in the labour market policies of OECD countries. Our results suggest that much of the variation in policy can be explained by different social objectives rather than by inefficient policy or differences in technology and human capital.

The analysis of this paper can be improved in two directions. First, the empirical assessment of the theory is only suggestive. An involved empirical study is needed to isolate the specific causes of policy variation across OECD countries. Second, the theory of the model could also be extended to incorporate a more detailed description of active labour market programmes. For example, different elements of active programmes, including different subsidies for training employed and unemployed workers, could be studied. We leave these improvements for further research.

7 Appendix

7.1 Solution Equivalence

This appendix shows that the decentralized economy is equivalent to the solution of a simple static maximization problem if the discount factor approaches unity. (1) The decentralized asset equations are given by

$$\Lambda = \frac{y + \beta\delta(V + \Pi)}{1 - \beta(1 - \delta)}$$

$$\Pi = 0$$

$$V = V(u) + (1 - e^{-\phi} - \phi e^{-\phi})(\Lambda - V(u))$$

$$\Pi = -k + e^{-\phi}(\Lambda - V(u)),$$

$$V(u) = a + \beta V$$

These equations for $\Lambda, V, V(u), \Pi$ and ϕ can rewritten to get a single expression for ϕ.

$$k = ye^{-\phi} + k(1 - \delta)\beta(e^{-\phi} + \phi e^{-\phi})$$

and that in the limit as β approaches 1 we get

$$k = ye^{-\phi} + k(1 - \delta)(e^{-\phi} + \phi e^{-\phi}) \tag{A1}$$

(2) Now consider the simple static problem of maximizing steady state output less recruiting costs. In this case

$$W = \max_{\phi} y(1 - u) + au - kv$$

such that

$$\phi = v/s$$

$$s = \frac{\delta}{\delta + (1 - \delta)(1 - e^{-\phi})}$$

$$u = s(1 - e^{-\phi})$$

The solution to this problem is the same as A1.

7.2 Relative slopes, dg/da and signs.

The slope, dg/db in the time-varying case is

$$\frac{dg}{da}|_{\text{time-varying case}} = \left(y_1^A - y_1^D\right) \frac{u_1^D}{1 - (1 - \delta) e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_0^A - u_1^D\right) >$$

$$\left(y_1^A - y_1^D\right) \frac{u_1^D}{1 - (1 - \delta) e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_1^A - u_1^D\right)$$

If $y_1^A = y_1^D$ then $\left(y_1^A - y_1^D\right) \frac{u_1^D}{1-(1-\delta)e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_1^A - u_1^D\right) = 0$. Increasing y_1^A then gives

$$\frac{\partial \left(y_1^A - y_1^D\right) \frac{u_1^D}{1-(1-\delta)e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_1^A - u_1^D\right)}{\partial y_1^A} = -\frac{\left(u_1^A\right)^2}{1 - (1 - \delta) e^{-\phi_1^A}} \frac{1}{\delta k} + \frac{\left(u_1^D\right)^2}{1 - (1 - \delta) e^{-\phi_1^D}} \frac{1}{\delta k} > 0$$

$$(25)$$

Then

$$\frac{dg}{da}|_{\text{time-varying case}} > 0$$

The slope, dg/da in the non-time-varying case is

$$\frac{dg}{da}|_{\text{non-time-varying case}} = u_0^A - u_1^A > 0$$

Relative slopes:

$$\frac{dg}{da}|_{\text{time-varying case}} > \frac{dg}{da}|_{\text{non-time-varying case}} \text{ iff}$$

$$\left(y_1^A - y_1^D\right) \frac{u_1^D}{1 - (1 - \delta) e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_0^A - u_1^D\right) > u_0^A - u_1^A \text{ iff}$$

$$\left(y_1^A - y_1^D\right) \frac{u_1^D}{1 - (1 - \delta) e^{-\phi_1^D}} \frac{\partial \phi_1^D}{\partial y_1^D} + \left(u_1^A - u_1^D\right) > 0$$

which is positive by (25).
