# Dispersion in Dispersion: Measuring Establishment-Level Differences In Productivity\*

We describe new experimental productivity statistics, Dispersion Statistics on Productivity (DiSP), jointly developed and published by the Bureau of Labor Statistics (BLS) and the Census Bureau. Official BLS productivity statistics provide information on aggregate productivity growth. Yet, a large body of research shows that within-industry variation in productivity provides important insights into productivity dynamics. This research reveals large and persistent productivity differences across businesses, even within narrowly defined industries. These differences vary by industry and time and are related to productivity-enhancing reallocation. Dispersion in productivity across businesses can provide information about the nature of competition and frictions within sectors, and about the sources of rising wage inequality across businesses. Because there were no official statistics providing this level of detail, BLS and the Census Bureau partnered to create measures of within-industry productivity dispersion. These measures complement official BLS aggregate industry-level productivity growth statistics and thereby improve our understanding of the rich productivity dynamics in the U.S. economy. The microdata underlying DiSP are available for use by qualified researchers on approved projects in the Federal Statistical Research Data Center network. DiSP confirms the presence of large productivity differences, and we hope that it will encourage further research into understanding these differences.

## 1. Introduction

In this paper, we describe new experimental productivity statistics, Dispersion Statistics on Productivity (DiSP), jointly developed and published by the Bureau of Labor Statistics (BLS) and the Census Bureau.<sup>1</sup> Productivity measures are critical for understanding economic performance in the U.S. economy. BLS produces the official labor and multifactor productivity growth statistics for major sectors and industries in the U.S. These statistics are constructed using aggregate industry-level data and can be thought of as changes in the first moment of establishment-level productivity (appropriately weighted). That is, these statistics show how productivity changes *on average* within sectors and industries, but they cannot provide insight into the *variation* in productivity levels across establishments within sectors or industries. Research has shown that changes in the dispersion of productivity across establishments in the same industry is related to changes in the growth of aggregate productivity (both economy wide and at the industry-level) through a variety of channels.

To fill this void, BLS and the Census Bureau initiated the Collaborative Micro-productivity Project (CMP) to develop and publish experimental statistics on within-industry productivity dispersion (i.e., second-moment measures of establishment-level productivity) and to produce restricted-use research datasets. The public-use statistics developed in this project—DiSP, which were released for the first time in fall 2019—cover all 4-digit NAICS industries in the manufacturing sector and are published jointly by BLS and the Census Bureau (1997–2016). Restricted-use establishment-level data with micro-based estimates of productivity and its underlying components (e.g., output and input measures) are also available to qualified researchers on approved projects in secure Federal Statistical Research Data Centers

---

<sup>1</sup> DiSP data are available on both BLS and Census Bureau websites at: <https://www.bls.gov/lpc/productivity-dispersion.htm> and <https://www.census.gov/disp>.

(FSRDCs).<sup>2</sup>

Economic theory and recent empirical evidence suggest that the second moments of productivity are informative on several important dimensions. One of the most important findings in the literature on micro-level productivity is that large productivity differences across establishments exist even within narrowly defined industries.<sup>3</sup> For example, using data from the 1977 Census of Manufactures (CM), Syverson (2004a) found that establishments at the 90<sup>th</sup> percentile of the within-4-digit-SIC productivity distribution are about four times as productive as those at the 10<sup>th</sup> percentile.

Syverson's findings generated considerable interest in the causes and consequences of this dispersion. Possible market explanations include curvature of the profit function that prevents the most-productive business from taking over an industry, frictions in factor adjustments (such as costs of adjusting input factors), barriers to entry and exit, and distortions that inhibit the equalization of marginal products across businesses (such as the regulatory environment). Drivers of establishment-level productivity variation include differences in management skills, the quality of production factors, innovation, and investments in R&D.

Research has shown that the dispersion of establishment-level productivity varies across sectors, by geographic area, and over time. For example, Syverson (2004a, 2004b) shows that variation in dispersion across industries and geographic areas is related to product substitutability, market structure, and competition. Hsieh and Klenow (2009) argue that both cross-country variation and within-country variation in the dispersion of productivity are related to distortions that inhibit productivity-enhancing reallocation. Asker, Collard-Wexler, and De Loecker (2014) present evidence that the patterns of dispersion reflect dynamic factor

---

<sup>2</sup> For more information on the FSRDCs: <http://www.census.gov/fsrdc>. An earlier version of this dataset was analyzed in Foster, Grim, and Haltiwanger (2016).

<sup>3</sup> Syverson (2011) provides a survey of this literature.

adjustment frictions within sectors. The findings in Foster, Grim, Haltiwanger, and Wolf (2016) suggest that productivity differences across establishments may be generated by differences in efficiency levels, demand shocks, frictions/distortions, or all of the above. Alternatively, Foster et al. (2021) and Cunningham et al. (2021) present evidence that industries experiencing a surge in innovation exhibit a burst of firm entry, followed by an increase in productivity dispersion during an experimentation and shakeout phase, followed ultimately by an increase in industry-level productivity.

Establishment-level productivity differences are also correlated with important economic outcomes at the micro level, such as the survival and growth of establishments. There is an extensive literature on the connection between productivity, reallocation, and growth (Baily, Hulten, and Campbell, 1992; Griliches and Regev, 1995; Foster, Haltiwanger and Krizan, 2001; Petrin, White and Reiter, 2011; Foster, Grim and Haltiwanger, 2016; Decker et al., 2020; Blackwood et al., forthcoming). These studies show that more productive businesses are more likely to survive and grow. These findings contribute to the perspective that reallocation—the process by which economic activity is allocated to its highest valued use—is an important contributor to aggregate productivity growth.

Productivity dispersion is also important for understanding rising wage inequality, which has been shown to be a between-firm phenomenon (Davis and Haltiwanger, 1991; Barth et al., 2016; Song et al., 2019; Haltiwanger and Spletzer, 2020). In addition, several studies have found that high-wage establishments are also more productive establishments and that rising between-establishment dispersion in wages is closely associated with rising between-establishment dispersion in productivity (e.g., Dunne et al., 2004). Economic theories of search and matching provide theoretical justification for the connection between productivity dispersion and wage dispersion (e.g., Burdett and Mortensen, 1998). Search and matching frictions create quasi-rents for worker-firm matches that make it optimal for high-productivity

firms to pay high wages.

Our results using the DiSP experimental data confirm earlier findings of sizeable differences in productivity across establishments within industries. To preview our results, we find that, on average, the manufacturing establishment at the 75<sup>th</sup> percentile of the within-industry labor productivity distribution is more than twice as productive as the establishment at the 25<sup>th</sup> percentile. If we instead focus on multifactor productivity, we find that the 75<sup>th</sup> percentile establishments are almost twice as productive as establishments at the 25<sup>th</sup> percentile. Underlying these averages, we find substantial differences in dispersion across industries. For example, labor productivity dispersion in the industry at the 75<sup>th</sup> percentile of the dispersion distribution is about 1.4 times as big as the dispersion in the industry at the 25<sup>th</sup> percentile. The corresponding multiplier for multifactor productivity is 1.2. We also find that dispersion in within-industry productivity exhibits a positive time trend over our sample period (1997–2016) and for multifactor productivity dispersion is significantly countercyclical.

The experimental statistics on productivity dispersion are intended to complement official BLS data, so it is crucial to understand the relationship between the dispersion of the productivity distribution derived from Census Bureau microdata and the statistics from BLS built from industry-level aggregates. Section 2 describes BLS productivity measures and productivity measures that we construct from Census microdata. Section 3 compares the two approaches to measuring inputs, output, and productivity for the manufacturing sector, and for 4-digit NAICS manufacturing industries. We also compare these measures to data from the NBER-CES Manufacturing Industry Database and examine several data and measurement issues such as imputation and weighting of the microdata. In section 4, we explore the variation in industry-level productivity dispersion measures across industries and over time. Section 5 summarizes our conclusions and describes plans for future work.

## 2. Measuring Productivity

Because our primary goal is to create statistics that provide insights about the official BLS industry-level productivity measures, it is useful to first describe how BLS constructs its measures from published aggregates, and then compare it to our measures that are constructed by aggregating Census microdata.

### 2.1. BLS Industry-level Productivity

BLS publishes quarterly and annual measures of labor productivity growth for major sectors; annual measures of labor productivity for 199 3-digit and 4-digit NAICS industries; and annual measures of multifactor productivity for major sectors, 18 3-digit NAICS manufacturing industries, 86 4-digit NAICS manufacturing industries, the air transportation industry, and the line-haul railroad industry. Productivity growth is measured as the difference between percentage changes in indexes of output and inputs (labor and, in the case of multifactor productivity, capital and intermediate purchases). BLS does not publish industry productivity levels, although they are available on request.

BLS industry output is based on a sectoral concept, which measures the value of goods produced for sale outside the industry.<sup>4</sup> For manufacturing industries, BLS uses published Annual Survey of Manufactures (ASM) and Census of Manufactures (CM) data on the total value of shipments, which it adjusts to remove intrasectoral transactions and resales and to account for changes in finished goods and work-in-process inventories.<sup>5</sup> This adjusted nominal output measure is then distributed to detailed categories of products and services using the mix

---

<sup>4</sup> Sectoral output is less than gross output, but greater than value-added output. In the most detailed industries, sectoral and gross output are the same or very close. However, going from very detailed industries to more aggregated industries, sectoral output moves closer to value-added output. In the limit, at the aggregate level, sectoral output is the same as value-added output, except for imported intermediate inputs. For more information on the importance of using sectoral output, see Kovarik and Varghese (2019).

<sup>5</sup> See <https://www.census.gov/programs-surveys/asm.html> and <https://www.census.gov/programs-surveys/economic-census.html>.

of annual wherever-made product shipments from the ASM. Nominal output in each product category is deflated using the appropriate detailed producer price index from the BLS prices program. These real output measures are then Tornqvist-aggregated into industry output indexes. Self-employment revenues for manufacturing firms, which come from Internal Revenue Service data, are also added to these output measures.

BLS measures labor input as the total annual hours worked by all persons in an industry. This measure is constructed by combining data from three BLS surveys: the Current Employment Statistics (CES) survey, the Current Population Survey (CPS), and the National Compensation Survey (NCS). The CES provides detailed information on the employment and average weekly hours *paid* for production and non-supervisory employees (henceforth referred to as production workers).<sup>6</sup> The NCS data are used to adjust CES average weekly hours from an hours-paid to an hours-worked basis by removing paid vacation accrued and sick leave taken.<sup>7</sup> To estimate nonproduction worker average weekly hours, BLS uses data from the CPS to calculate a ratio of nonproduction to production worker average weekly hours worked, which is then multiplied by the adjusted CES production worker hours (worked). Total nonproduction worker hours are estimated as:

$$TH_{NP} = \text{Emp}_{NP}^{\text{CES}} \times \text{AWH}_p^{\text{CES}} \times hwhp_p^{\text{NCS}} \times \frac{\text{AWH}_{NP}^{\text{CPS}}}{\text{AWH}_p^{\text{CPS}}} \times 52 \quad (1)$$

where  $\text{Emp}_{NP}^{\text{CES}}$  is nonproduction worker employment from CES,  $\text{AWH}_p^{\text{CES}}$  is production worker average weekly hours paid from CES,  $hwhp_p^{\text{NCS}}$  is the hours-worked-to-hours-paid ratio from NCS, and  $\left(\frac{\text{AWH}_{NP}^{\text{CPS}}}{\text{AWH}_p^{\text{CPS}}}\right)$  is the CPS nonproduction/production average weekly hours ratio. CPS data are also used to construct hours worked by self-employed and unpaid family workers (Eldridge,

---

<sup>6</sup> Workers in goods-producing industries are referred to as being production or non-production workers and in the service-providing industries as nonsupervisory or supervisory workers.

<sup>7</sup> Note that this adjustment does not account for off-the-clock hours.

Manser, and Otto, 2004).

For multifactor productivity at the 4-digit NAICS level, capital input is based on the flow of services from the productive stock of capital. BLS investment data for industries combine expenditures on structures and equipment from the ASM with data on investment in different assets by industry from BEA and the Annual Capital Expenditure Survey (ACES). Using a perpetual inventory method, BLS then computes industry-asset level capital stocks from these investment flows. In BLS official multifactor productivity measures, these stocks are converted to capital services using industry-asset specific rental prices and then aggregated to the industry level.

For intermediate purchases inputs, BLS combines quantities of materials, purchased business services, fuels, and electricity consumed by each industry. The nominal values of materials, fuels, and electricity are from the CM and ASM, while the values of purchased business services are estimated from BEA and Census Bureau data.

## *2.2. Establishment-level Productivity using Census Data*

To measure establishment-level labor productivity, we combine establishment-level information from three Census Bureau restricted-use microdata files with public-use industry-level data from BLS. Given that one goal of our research is to shed light on BLS industry productivity statistics, we try to match BLS concepts and measures as closely as possible.

Our establishment-level microdata come from the CM, the ASM, and the Longitudinal Business Database (LBD). The CM is collected every 5 years in years ending in '2' and '7'. Data are collected from all manufacturing establishments except those that are very small. For these very small out-of-scope establishments, the Census Bureau imputes data using administrative records. The ASM sample is a 5-year panel of manufacturing establishments, updated every year for births, and data are collected annually. ASM panels begin in years ending

in ‘4’ and ‘9’, and the probability of selection into the ASM sample is a function of both industry and size (employment or the value of shipments). Like the CM, the ASM does not collect data from very small establishments but accounts for them using administrative information. In CM years, ASM data are collected as part of the CM data collection, but for this analysis and the public-use statistics, we use only the ASM establishments.<sup>8</sup> Data are imputed for establishments that do not respond or that fail to report some data elements (item non-response); we discuss this further in section 2.3. The LBD is a longitudinally linked version of the Census Bureau’s Business Register that covers the non-agricultural employer universe of business establishments (see Chow et al., 2021 and Jarmin and Miranda, 2002). The LBD provides us with both high-quality longitudinal links and information on the universe of manufacturing establishments, which we use to construct the propensity-score weights that we use in our productivity calculations.

Ideally, we want to construct an output measure that exactly matches the BLS measure. We start by using Census microdata to replicate the value of shipments as closely as possible. Specifically, we calculate establishment-level real output as deflated revenues, adjusted for resales and changes in inventories.<sup>9</sup> However, we cannot replicate the BLS sectoral output concept because the ASM does not collect the information needed to calculate intra-sectoral transactions. Instead, we add the value of intra-sectoral transactions back into BLS output measures to make the two measures comparable. Thus, we measure establishment-level output as:

$$Q_{et} = (TVS_{et} + DF_{et} + DW_{et} - CR_{et})/PISHIP_{it} \quad (2)$$

where  $TVS$  = total value of shipments,  $DF_{et} = FIE_{et} - FIB_{et}$  and  $DW_{et} = WIE_{et} - WIB_{et}$  are

---

<sup>8</sup> The microdata made available in the FSRDCs contains productivity measures for all CM establishments when productivity calculation is possible.

<sup>9</sup> In practice, subtracting resales does not make much difference because they are only a small fraction of revenue.

the changes in finished-goods and work-in-process inventories, respectively ( $FIB$ ,  $FIE$  = beginning-of-year and end-of-year finished goods inventories, and  $WIB$ ,  $WIE$  = beginning-of-year and end-of-year work-in-process inventories),  $CR$  = cost of resales,  $PISHIP$  = deflator for the value of shipments, and the  $i$ ,  $e$ , and  $t$  subscripts index industries, establishments, and years, respectively.<sup>10</sup>

We measure labor input as total hours worked. For each establishment, the ASM collects the total number of employees, the number of production workers, and the total number of hours worked by production workers. We calculate total annual hours worked by summing ASM production worker hours and an estimate of nonproduction worker hours, which we calculate using the same methodology as BLS (equation 1) but substituting ASM data for CES:<sup>11</sup>

$$TH_{et} = PH_{et} + \left( (TE_{et} - PW_{et}) \times \frac{PH_{et}}{PW_{et}} \times \left( \frac{AWH_{NP}^{CPS}}{AWH_P^{CPS}} \right)_{it} \right) \quad (3)$$

where  $PH$  = production worker hours,  $PW$  = the number of production workers,  $TE$  = total employment, and  $\frac{AWH_{NP}^{CPS}}{AWH_P^{CPS}}$  = CPS non-production/production average weekly hours ratio for the 4-digit NAICS industry. We calculate establishment-level log labor productivity as:

$$\ln LP_{et} = \ln Q_{et} - \ln TH_{et}. \quad (4)$$

Establishment-level multifactor productivity (MFP) in logs is measured as:

$$\ln MFP_{et} = \ln Q_{et} - \alpha_K \ln K_{et} - \alpha_L \ln TH_{et} - \alpha_M \ln M_{et} - \alpha_E \ln E_{et}, \quad (5)$$

where  $Q$  and  $TH$  are real output and total hours as defined above in (2) and (3),  $K$  denotes real productive capital stock, and  $M$  and  $E$  denote deflated values of expenditures on materials and

<sup>10</sup> The shipments deflator is from the NBER-CES dataset. Values for 2012-2016 are imputed using price indexes from BEA GDP-by-Industry data. In comparisons to BLS output data conducted in this paper, BLS industry implicit output price deflators (as described in 2.1) are used in place of the shipments deflator.

<sup>11</sup> Note that it is not necessary to use the hours-worked-to-hours-paid ratio because establishments are requested to report hours worked.

energy, respectively.<sup>12</sup> The productive capital stock is constructed using the perpetual inventory method for equipment and structures separately.<sup>13</sup> The value of  $M$  is calculated as the deflated sum of cost of materials, the cost of resales, and the cost of contract work done for the establishment by others.<sup>14</sup> The nominal value of  $E$  is the sum of the cost of electricity and the cost of fuels. For the CMP data ultimately included in the DiSP data, the two expenditures are deflated using the appropriate deflators from the NBER-CES database. We measure the factor elasticities,  $\alpha_K$ ,  $\alpha_L$ ,  $\alpha_E$ , and  $\alpha_M$ , using the share of expenditures of the corresponding input in total cost in each 6-digit NAICS industry.<sup>15</sup> For the BLS data comparisons, we use published BLS industry cost shares; for the DiSP statistics, we use shares calculated from CMP data.

DiSP does not include value-added-based productivity dispersion for conceptual reasons. While there is a market for final demand, a market for value-added does not exist. This consideration is irrelevant for the overall economy, because value added equals the value of final demand at that level of aggregation. However, the relationship between value added and final demand is only an approximation at lower levels of aggregation. In order to make inferences about final goods produced by an establishment or industry, not only are the output and input values necessary but also the relevant input-output linkages.<sup>16</sup> A related issue is that

---

<sup>12</sup> BLS constructs aggregate MFP using capital services rather than productive stock.

<sup>13</sup> We do not include rented capital due to its irregular collection in the ASM. Pre-1986 and post-2006, this information is collected annually on the ASM. In the intervening years, this information was only collected in the Economic Census. Exploratory analysis for the years when this is available shows rented capital is small and does not make much difference to establishment-level capital measures. We plan on exploring this further in future research.

<sup>14</sup> Published ASM measures of value-added are based on the difference between the value of output and a composite operating expenses measure inclusive of materials and energy expenditures. We break out the cost of materials and energy separately in our MFP measure. The inclusion of contract work implies that some aspects of purchased services are included in the materials expenditures. However, since 2006, the ASM has included questions on other operating expenses, including leased employees and additional purchased services not included in the cost of contract work. We are actively exploring the inclusion of those operating expenses for a supplemental multifactor productivity dispersion measure commencing in 2006. Challenges for inclusion of these variables are the short time series, item non-response rates, and the treatment of establishments of single unit versus multi-unit firms. Establishments of the latter are less likely to have such additional operating expenses because the headquarters establishment of the parent firm may be providing and/or purchasing those services.

<sup>15</sup> See web appendix B in Foster, Grim, and Haltiwanger (2016) for more details. Procedures for extending the output and input price deflators are described in this appendix.

<sup>16</sup> An additional consideration follows when using the logarithmic transformation to stabilize the variance of

the existence of a value-added production function at the establishment-level requires very strong functional form assumptions that are likely violated (Basu and Fernald, 1997).

### *2.3 Missing Data and Imputation*

As noted earlier, the ASM microdata are subject to item non-response, and these missing values are imputed by the Census Bureau. The Census Bureau’s imputation methods are designed to yield accurate published aggregates but do not necessarily preserve the distribution or adequately reflect the variability of the underlying microdata. There is evidence that certain imputation methods may affect microdata analyses. However, there are techniques available to mitigate the effects of imputation on dispersion measures. For example, White, Petrin, and Reiter (2018) analyze dispersion statistics using classification and regression-tree methods. Foster et al. (2017) follow a different approach and address imputation by dropping observations with imputed data and reweighting the remaining observations. The results from these studies suggest that imputation yields lower measured dispersion relative to the case when imputation is corrected for. In this paper, we use the entire set of observations in the sample and leave further analysis of these issues for future work.

## **3. Comparing Micro-Aggregated Data to Published Industry Data**

In this section, we compare our micro-aggregated estimates to the official data published by BLS, covering the 1997–2016 period. Based on earlier work comparing similar business data across the two government agencies, we expect that there will be some systematic differences between these measures (Elvery et al., 2006). Even though differences in the levels of the micro-aggregated and published first moments do not directly affect our conclusions about

---

empirical distributions. This transformation truncates distributions at zero, which leads to biased inference if the probability of negative value added is correlated with establishment-level characteristics. Negative value-added may be plausible, for example, in intermediate-intensive industries during periods of recession or crises (Cao, Fox, and Soriano, 2021).

dispersion (because we control for industry-year effects), it is useful to determine how far apart the two sets of estimates are. If the first moments are close, then it is more reasonable to think of the micro-based second moments as measuring variation around the published first moments. As an additional check, we compare these two sets of estimates to estimates from the NBER-CES database. The NBER-CES estimates can be thought of as equivalent to the official published ASM and CM statistics upon which they are based and are used here for comparison only.<sup>17</sup> We start by comparing input and output measures, and then we compare productivity measures.

### *3.1. Input and Output Measures*

Figure 1 shows the total number of employees in the manufacturing sector from each series. The first thing to note is that employment levels based on ASM microdata (using ASM sample weights) are significantly lower than the published ASM and BLS estimates because they exclude the “non-mail” stratum—small establishments that are not sampled by the ASM. The published ASM series includes adjustments for the non-mail stratum and is much closer to the BLS estimates.

To account for these small out-of-scope establishments, we construct an alternative set of weights that augment the sample weights. As noted, the weighted sample total calculated from the ASM (using ASM sample weights) is by design not equal to the published total because there are additional adjustments in the latter for the non-mail cases. Fortunately, there are some very small establishments in the ASM sample each year that are below the thresholds for non-mail cases. This occurs because, among the smaller establishments that were selected for the ASM (that is, establishments with employment above the threshold), some had fallen below the size threshold by the time that they provided data. This implies that there is coverage

---

<sup>17</sup> For more information on the NBER-CES Manufacturing Industry Database, see <http://www.nber.org/nberces/>. The NBER-CES series was last updated through 2011 as of September 15, 2020.

for all business sizes in the ASM sample (e.g., there are ASM establishments in any given year and industry with 1–4 employees, even though this is typically below the ASM sample threshold). To create the alternative set of weights, we use the LBD. Specifically, we define the manufacturing universe using the LBD and use LBD data to estimate the probability that an establishment is included in the ASM sample. We then use these probabilities to construct inverse propensity score weights (PSW). See Appendix B for a full discussion of the weighting procedures. This procedure increases the weights assigned to the “non-mail” establishments so that the propensity-score-weighted employment totals are consistent with the LBD.<sup>18</sup> Moreover, as seen in Figure 1, the micro-aggregated employment series using PSW yields totals that align with the published BLS and ASM more closely than those using ASM weights.<sup>19</sup> This aligns with our objective in using PSW, as these weights correct for the contribution of the “non-mail” establishments in a manner that the ASM weights are not designed to address.

Next, we compare total manufacturing output and input growth across the BLS, CMP–PSW, and NBER series (Figure 2).<sup>20</sup> For all three series, we use the BLS price deflators for these comparisons, apart from the capital series, because BLS does not produce separate deflators for equipment and structures. To make it comparable to what we can construct from the ASM, we also adjust the BLS output series by adding the value of intrasectoral transactions back into the series. The BLS and NBER output series track each other closely, while the CMP series deviates from the other two series in some years but exhibits the same pattern of growth rates (see Panel (a)). Panel (b) of Figure 2 compares hours growth rates, which exhibit similar dynamics across the series, except during the 2005–2007 period, when the NBER series

---

<sup>18</sup> In addition, unreported results suggest that PSW do a good job matching the industry/year-specific size and age distributions of the LBD.

<sup>19</sup> We explored the possibility of benchmarking CMP employment (based on the manufacturing universe in the Census Business Register) to BLS employment (based on the manufacturing universe in the BLS Quarterly Census of Employment and Wages). While this benchmarking would improve the correlation between the BLS and CMP labor (employment and hours) measures, it decreases the correlation between BLS and CMP output and the other input measures, which are based on the manufacturing universe in the Census Business Register.

<sup>20</sup> See Appendix A Table A1 for further details about the construction of these series.

diverges. Panel (c) of Figure 2 shows capital stock growth rates. All three series exhibit a slight downward trend in the late 1990s and are essentially flat starting in the early 2000s. Panels (d) and (e) of Figure 2 show that for energy and material inputs, the three series track very closely.<sup>21</sup>

Table 1 shows correlations between the three data sources for inputs and output for the total manufacturing sector. The correlations in the top panel are based on total manufacturing aggregate time series, while the bottom panel shows the average of the within-industry correlations for 4-digit NAICS industries, calculated over the 19 years of the sample. The top panel of the table shows that hours, energy, materials, and output, both in levels and in growth rates, are highly correlated across the data series (the correlations range from 0.88 to 0.99). Average industry-level correlations, shown in the bottom panel, are lower than for total manufacturing, but they are still reasonably high for these variables, both in levels and in growth rates.

The correlation between the capital series is significantly lower than the correlations described above. There are several plausible explanations. First, there is a fundamental difference in the underlying data. BLS investment data for 4-digit industries combine expenditures on structures and equipment from the ASM with data on investments in different assets by industry from BEA and the Annual Capital Expenditures Survey (ACES).<sup>22</sup> Using a perpetual inventory method, BLS then computes industry capital stocks from these investment flows. In contrast, our approach takes investment flows directly from the establishment and uses these flows with the perpetual inventory method at the establishment level to generate capital stocks. Second, the BLS investment series covers a longer period than the micro-aggregated series. This is significant, because initial capital stocks are difficult to measure. The BLS capital stock is built up from investment flows that stretch back to 1958 (and longer for some assets).

---

<sup>21</sup> The cost of purchased services and resales are not included in the materials comparisons.

<sup>22</sup> See Becker et al. (2006) for more discussion of the relationship between top-down methods used by the BEA and bottom-up methods like those we use with the establishment-level data for measuring capital stocks and flows.

By 1997, when our data series starts, the BLS capital stock reflects mainly investment, and the impact of any mismeasurement of the initial capital stock is minimal. In contrast, the sample rotation in the ASM implies that we need to estimate initial capital stocks for establishments that newly enter the sample rotation. For CMP, we initialize new establishments using their book value, and the earliest book value and investment data that we use dates to 1972. Despite differences in data sources and methodologies, we can conclude that the micro-aggregated data are largely consistent with published aggregate data.

### *3.2. Productivity Growth*

We calculate productivity growth as the change in log productivity where productivity is measured as either output per hour or multifactor productivity.<sup>23</sup> Figure 3(a) shows that output-per-hour growth rates for the manufacturing sector are broadly similar, but with some greater discrepancies in various subperiods (e.g., 2003–2009). These differences can be attributed to the differences in data sources and methodologies, some of which were illustrated in Figure 2. Despite underlying differences, multifactor productivity growth shows remarkable similarity across these data sources, see Figure 3(b). Table 2 echoes these findings: the correlations between the series constructed using different data sources are highest for multifactor productivity growth.

This comparison of inputs, output, and productivity serves as an important backdrop to our new experimental statistics on within-industry dispersion. Although there are some differences between the BLS aggregates and the micro-aggregated series, they are similar enough to allow us to make meaningful inferences about the relationship between within-industry dispersion and BLS published estimates of industry productivity growth.

---

<sup>23</sup> The official BLS productivity series are calculated using percentage changes in the index, and thus the BLS series that we refer to here differ slightly from the published series. Additionally, the official total manufacturing productivity series is published by the BLS Division of Major Sector Productivity, whereas the data here are aggregated from industry data provided by the BLS Division of Industry Productivity Statistics.

#### 4. Productivity Dispersion

For our analysis of productivity dispersion, we focus on levels rather than growth rates. Because we are interested in comparing within-industry dispersion of productivity across industries and over time, it is necessary to account for industry differences in average productivity. To do this, we calculate establishment-level productivity as the deviation from average productivity in that establishment's 4-digit industry in each year.<sup>24</sup> The interpretation of normalized productivity levels is intuitive: they tell us how far above or below the mean the establishment sits in the productivity distribution.

We use the interquartile range (IQR) as our primary measure of dispersion, because it is intuitive and easy to interpret. The IQR shows how much more productive an establishment at the 75<sup>th</sup> percentile of the productivity distribution is than an establishment at the 25<sup>th</sup> percentile of the productivity distribution. The standard deviation may seem like an obvious alternative to the IQR; however, it is known to be more sensitive to outliers than quantile-based dispersion measures. We also report the 90-10 differential as well as the 10-1 and 99-90 differentials.

Table 3 shows the descriptive statistics of the distribution of dispersion measures.<sup>25</sup> The first entry reported in the table (0.898) says that in the average industry and year, establishments at the 75<sup>th</sup> percentile of the distribution are about ( $e^{0.898} \approx$ ) 2.45 times as productive as those at the 25<sup>th</sup> percentile. Establishments at the 90<sup>th</sup> percentile are about 5.9 times as productive as those at the 10<sup>th</sup> percentile. Average dispersion in multifactor productivity is lower.<sup>26</sup> However, establishments at the 75<sup>th</sup> percentile are still about 1.7 times as productive as those at the 25<sup>th</sup> percentile using multifactor productivity measures. This implies substantial differences in a core measure of business performance at the establishment-level within narrowly defined industries.

---

<sup>24</sup> These are weighted averages using PSW where establishment-level productivity is expressed as a deviation from average productivity in that establishment's 4-digit NAICS industry.

<sup>25</sup> We present standard deviations in Table 3 but do not discuss these results.

<sup>26</sup> The range for output per hour is somewhat larger than what was found by Syverson (2004a)—he found a multiplier of about 1.9—but our findings are generally in line with his results.

Many factors may underlie the observed dispersion in measured productivity across establishments in the same industry.<sup>27</sup> We define a “wedge” as any mechanism that prevents equalization of marginal revenue products across producers. Because the measures of productivity dispersion reported here are revenue-based, the presence of widespread dispersion is consistent with the presence of some form of wedges. One form is adjustment frictions that inhibit businesses from adjusting their scale of operations and specific inputs to changing economic conditions. These adjustment frictions may be related to the costs of adopting new technologies or business practices; thus, dispersion in an industry may reflect the gap between the frontier establishments and other producers. Additional sources of wedges are market distortions such as differences in markups across producers or financial constraints in the same industry. Complicating matters is that in the presence of wedges that are correlated with fundamentals, the variation in the dispersion will also reflect differences in business fundamentals such as technical efficiency and product appeal across businesses (Blackwood et al., forthcoming). For example, an increase in the dispersion in product appeal across producers in the presence of adjustment frictions will yield an increase in dispersion of revenue productivity across producers (even if the adjustment frictions remain constant). In a similar fashion, dispersion may reflect unmeasured inputs. These could include production methods, management practices, and the mix of worker types (labor quality). Rising revenue productivity dispersion might also reflect rising dispersion in firm-level markups (DeLoecker, Eeckhout, and Unger, 2020; Foster, Haltiwanger, and Tuttle, 2021).

It is well beyond the scope of the current paper to determine the relative importance of each of these alternative factors. Instead, the aim here is to describe the DiSP data product and point to its potential for investigating these alternative determinants of dispersion. One strength

---

<sup>27</sup> See Syverson (2011) for more detailed discussion of these issues and Blackwood et al. (forthcoming) for a discussion more closely related to this new data product.

of the new data product is that dispersion measures are provided at a detailed level of aggregation by year. Figure 4a summarizes how within-industry dispersion in output per hour—measured as the IQR—varies across industries and over time. The mean and median IQR are close to each other, but the large differences between the 25<sup>th</sup> and 75<sup>th</sup> percentiles show that there is substantial variation in the IQR across industries. For example, in 2002, the productivity difference between establishments at the 75<sup>th</sup> and 25<sup>th</sup> percentiles is about 100 log points in the industry at the 75<sup>th</sup> percentile of the IQR distribution, while this difference is approximately 70 log points in the industry at the 25<sup>th</sup> percentile of the IQR distribution. We find similar differences across the industry distribution when looking at multifactor productivity dispersion, with IQRs of approximately 60 and 40 log points at the 75<sup>th</sup> and 25<sup>th</sup> percentiles, respectively (see Figure 4b).

The differences in the IQRs suggest that there are factors such as those discussed above that generate “dispersion in dispersion,” including differences in shocks, adjustment costs, distortions, technology, and distributions of capital intensities. In addition, dispersion is rising during the period under investigation, more so for multifactor productivity than for labor productivity. The rising trend suggests that wedges, and the dispersion in business fundamentals underlying the observed dispersion, are changing in systematic ways over time.<sup>28</sup> We can also see from Figure 4 that although the volatility of (the mean) dispersion is non trivial, it is dwarfed by the variation across industries. Table 4 shows that there is substantial churning in the ranking of industries in terms of their dispersion. This finding highlights that not only is there dispersion in dispersion but the cross-sectional variation across industries varies over time.

For the rest of this section, we consider a few extensions to our analysis to illustrate

---

<sup>28</sup> There is an ongoing debate about the source of the rising dispersion in revenue productivity measures. See, e.g., [Bils, Klenow, and Ruane \(2020\)](#), [Blackwood et al. \(forthcoming\)](#) and [Decker et al. \(2020\)](#). We do not seek to address that debate here directly but note that [Decker et al. \(2020\)](#) find that rising (revenue-based) labor productivity dispersion in manufacturing is present in both the ASM data used here and in administrative data from the Business Register. This finding suggests that an increase in measurement error is not driving the rising dispersion.

further the nature of the dispersion. We first examine how our results change when we weight establishments using activity weights. Activity weights are generated by multiplying our PSWs by an activity measure such as hours shares (the share of an establishment's hours of the total hours in its industry) for labor productivity and composite input shares for multifactor productivity. Activity weighting paints a potentially different picture of dispersion because there may be differences between the dispersion of different size groups. Our second extension is to examine the tails of the productivity distribution. There has been great interest in the finding that a substantial portion of wage inequality is driven by the upper tail of the distribution and by increasing between-establishment wage differentials. Investigating the upper tail of the productivity distribution is analogously interesting, as theory and evidence show that the productivity and earnings distributions are related. Third, we explore the common secular trends and cyclicalities in the dispersion measures. Fourth, we highlight that most of the within-industry dispersion in productivity is not accounted for by establishment observables like business size, age, or location. Finally, we provide additional information about the public domain DiSP data product.

#### *4.1. Activity-Weighted Dispersion Measures*

Figure 5 replicates the dispersion measures in Figure 4 but using activity weights, which we will refer to as “activity-weighted” distributions. We see rising dispersion over time in both Figures 4 and 5. The main difference is that activity-weighted dispersion is smaller and exhibits less year-to-year variation than dispersion weighted by PSW alone. Because activity weights give more weight to larger establishments, comparison of Figures 4 and 5 implies that there is less dispersion among larger establishments. Or put differently, dispersion in productivity across hours or composite inputs is lower than dispersion across establishments. Activity-weighted dispersion also exhibits a rising trend that is more pronounced than the increase in

trend dispersion without activity weighting.

#### *4.2. Dispersion in the Tails*

Turning to the tails of the productivity distributions, a distinctive feature of the within-industry productivity distribution is that mean and median dispersion in the right tail (the 99-to-90 difference—see Figure 6) are about the same order of magnitude as the mean and median dispersion of the IQR (see Figure 4). This is striking given that each tail covers only one-fifth as many establishments as the IQR. Comparing Figure 6a to Figure 4a, output per hour dispersion in the 99-to-90 difference is only slightly smaller than the IQR. Multifactor productivity 99-to-90 differences are even larger than the IQR. In addition, differences in the right tail of the multifactor productivity distribution are rising faster: the mean shows that dispersion in the right tail rose by about 40 log points between 1997 and 2016 while the IQR rose by only 10 log points over the same time period (compare Figures 6b and 4b). The weighted dispersion measures (Figure 7) generally show similar patterns but a smaller absolute increase. In addition, there is substantial dispersion in dispersion in the right tail.

In contrast to the right tail, the left tail (the 10-to-1 ratio) exhibits lower dispersion relative to the IQR. Mean output-per-hour 10-to-1 differences are 20–30 log-points smaller than the IQR, though they exhibit similar volatility (see Figure 8a). Mean multifactor productivity differences in the left tail are similarly smaller initially than the IQR and exhibit no positive trend (see Figure 8b).<sup>29</sup> The weighted dispersion measures tell a similar story (Figure 9).

These findings highlight the importance of looking at the entire productivity distribution. The IQR is a convenient measure that covers half of the distribution. However, there is as much dispersion in the upper and lower tails as there is in the center of the distribution. We also see

---

<sup>29</sup> The spike in mean dispersion in 1998 is due to transitory changes in the following 4-digit NAICS industries: 3341, 3342, 3344, 3345, and 3351. In these industries, the least productive establishments shifted to the left in 1998 and then back to the right in 1999. The significant changes in production technologies in these industries (factoryless manufacturing and offshoring) may explain these transitory dynamics in these years.

that weighting matters: accounting for size tends to reduce both productivity dispersion and its volatility.

#### *4.3. Common Secular Trends and Cyclicalities in Dispersion*

As is evident in Figures 4 and 5, the moments of industry-level dispersion exhibit considerable variation over time with an apparent upward trend in the first moment. Table 5 quantifies common trends and cyclicalities in the IQR measures of labor productivity and multifactor productivity on both an activity-weighted and non-activity-weighted basis. These regression results are based on the public-domain DiSP panel data at the 4-digit-NAICS-by-year level. All reported results include (unreported) industry fixed effects. A statistically significant positive trend is present for all measures considered. Cyclicalities are captured by the change in the national unemployment rate (Bureau of Labor Statistics 1996–2016). Periods of increases in the unemployment rate correspond closely to NBER-defined recessions (Foster, Grim, and Haltiwanger, 2016). Dispersion in multifactor productivity is significantly countercyclical in the DiSP data, which is consistent with Kehrig (2015). Dispersion in labor productivity has a less consistent cyclical pattern. It is significantly procyclical when using the non-activity weighted dispersion measure, but acyclical using the activity-weighted dispersion measure.

#### *4.4. Establishment and Firm Characteristics and Within-Industry Dispersion*

Many factors may underlie the substantial dispersion in productivity measures across establishments within the same industry as well as the variation in the dispersion measures between measures over time. To provide more guidance on the potential driving forces, we examine the relationship between productivity and observable establishment characteristics. For this purpose, we examine differences across space (by state), establishment size, and age.

Table 6 shows the R-squared and p-values from F-tests for regressions of establishment-level productivity on observable establishment characteristics, such as geography

(state), size, and age classes. We focus on accounting for the variation in productivity within (4-digit NAICS) industry cells. While we find that geography, size, and age have statistically significant relationships with productivity variation across establishments in the same year and industry, such characteristics account for only a fraction of the observed differences in the productivity levels across establishments. It is this type of finding that highlights the interpretation in the research literature that there is enormous idiosyncratic variation in measured productivity across establishments. As we have discussed above, such idiosyncratic variation may stem from many factors. Further research is necessary to understand the contribution of different factors to this idiosyncratic dispersion, and we hope that the DiSP data product will prove useful in this regard.

#### *4.5 Description of the Dispersion Statistics on Productivity (DiSP) Data Product*

The new data product, Dispersion Statistics on Productivity (DiSP), which will be updated annually,<sup>30</sup> contains a balanced panel of productivity statistics summarizing the within-industry distributions of output per hour and multifactor productivity. Dispersion statistics include standard deviations, interquartile and interdecile ranges of the within-industry distributions of establishment-level productivity. All data moments are weighted using the PSW so that they are representative of the universe of establishments (see sections 2.2 and Appendix B.2). In addition, the dataset includes activity-weighted versions of dispersion measures. The 99-to-90 and 10-to-1 ranges are currently under consideration for future releases, given the interesting patterns in the right and left tails highlighted above.

The data product will be useful in analyzing the relationships between productivity dynamics at the establishment-level, industry-level, and for the entire manufacturing sector. As

---

<sup>30</sup> The timeliness of the data depends on the release of establishment- and firm-level information. In non-Census years, the ASM is available in the fall of the following year, while the LBD becomes available in spring of the year after that. In Census years, microdata become available later. The productivity dataset can be created approximately 2–3 months after the underlying microdata becomes available.

discussed above, many factors may underlie the cross-industry and time-series variation in dispersion. We expect that this new data product will facilitate our understanding of the connection between micro- and macro-level productivity. A key benefit of making these data available will be to allow researchers without access to the confidential microdata to explore the various possible causes—and effects—of the differences in within-industry dispersion across industries and over time.

## **5. Concluding Remarks**

A growing literature uses micro-level data to examine establishment-level productivity dynamics and finds substantial within-industry productivity dispersion. This paper provides an overview of a new data product, Dispersion Statistics on Productivity (DiSP), released jointly by BLS and the Census Bureau. This new data product provides measures of productivity dispersion within narrowly defined industries by year.

Much of the paper discusses the methodology used to produce this data product. We compare our input and output measures, which we aggregated from micro-level data, to official BLS aggregates at the industry and manufacturing-wide level. Not surprisingly, we find some differences between BLS industry-level data and micro-aggregated ASM data. However, in general, we find high correlations between BLS and micro-aggregated outputs and inputs (for example, at the total manufacturing level, the correlation between the BLS published series and the micro-aggregated data for output and hours growth are both about 0.9).

Using measures of inputs and output, we develop measures of labor productivity (output per hour) and multifactor productivity (output per unit of combined inputs) and examine some of their properties. Correlations between BLS and micro-aggregated labor productivity growth are also reasonably high and especially high for multifactor productivity growth (e.g., at the total manufacturing level, the MFP growth correlation is 0.94).

Illustrating the properties of the new data product, we find large within-industry dispersion in labor productivity: establishments at the 75th percentile are about 2.4 times as productive as those at the 25<sup>th</sup> percentile, on average. For multifactor productivity, we find that the analogous ratio is 1.7. These patterns show enormous differences in measures of business performance across establishments in the same narrowly defined industry and year. Differences might stem from many factors, but they highlight both great potential for growth (e.g., if the gaps between high- and low-productivity businesses could be reduced) and also possible sources of frictions or distortions that are impeding a more efficient allocation of resources.

As the title of our paper alludes to, we find significant dispersion in within-industry dispersion across industries. For the top quartile of industries, the ratio of multifactor productivity across establishments implied by the IQR exceeds 1.7, while for the bottom quartile of industries the ratio is lower than 1.4. Dispersion in dispersion over time is small in comparison but is still important. As has been found in prior academic literature, we find rising dispersion in both labor productivity and multifactor productivity, and that multifactor productivity dispersion is countercyclical.

Our results also indicate that average dispersion depends on where we measure it: average dispersion is greater as we move further away from the center of the support of the within-industry productivity distribution. Specifically, average productivity differences across establishments (especially for multifactor productivity) are largest in the right tail of the productivity distribution. Similar to what we find for average dispersion, the dynamics of these measures depend on where we measure productivity differences. We find evidence that dispersion among the most productive establishments has been increasing during our sample period, while differences among the least productive establishments do not show these patterns. This suggests that positively trending dispersion found in earlier studies may be a consequence of the dynamics among the most productive establishments. Our analysis suggests that these

patterns are sensitive to how dispersion is measured. We find that activity weights generally imply smaller, less volatile productivity differences among establishments in the entire distribution. We also find that, on average, weighted dispersion among more productive establishments shows a more pronounced positive trend.

In future work, we plan to explore extending the data product in several directions. As noted, one active area of exploration is releasing statistics on the tails of the productivity distribution. Another area of exploration is to release statistics by additional characteristics, such as firm age and firm size. Research has shown that young businesses exhibit especially high productivity dispersion. This may reflect greater experimentation by young businesses as well as greater challenges that young businesses face in changing their scale of operations.

## Appendix B

### *B.1. Properties of ASM samples*

The ASM is a 5-year panel of roughly 50,000–70,000 manufacturing establishments. It is a sample of establishments drawn from the manufacturing portion of the Census Bureau’s Business Register using a probability proportional to size sampling scheme.<sup>31</sup> The largest establishments are sampled with certainty and are included in every panel.<sup>32</sup> Smaller establishments are sampled with a probability less than one, where the probability increases with establishment size (measured by the value of shipments). The smallest single-unit establishments, which are part of the “non-mail” stratum, are not mailed a form but they are included in the estimates. Because of the desire to reduce reporting burden, the Census Bureau uses administrative records to impute payroll, employment, industry, and location from the administrative data for the smallest single-unit establishments, while total value of shipments is imputed using industry averages.<sup>33</sup>

The ASM sample is refreshed every 5 years. New ASM panels are drawn from the Economic Census and begin 2 years after the Census from which it was drawn (years ending in 4 and 9). The sample is also updated annually to include new establishments which are identified on the Census Bureau’s Business Register. The Business Register is updated with information from the Economic Census as well as administrative records from the IRS and the

---

<sup>31</sup> For more information about the ASM see <http://www.census.gov/manufacturing/asm/>.

<sup>32</sup> Prior to 1999, certainty units were establishments with 250 or more employees. In 1999, the cutoff was increased to 500 employees and, in 2004, it was increased again to 1,000 employees. Currently, the 10 largest establishments in an industry are also sampled with certainty. In addition to establishment size, certainty criteria include other characteristics such as industry, cell size, or energy use. For example, Computers, Flat-glass, Sugar, and Small industries (with less than 20 establishments), or establishments with large inventories, assets, fuel/electric expenditures are also sampled with certainty.

<sup>33</sup> Non-mail cases are included in the official estimates and have a weight of one. The survey is designed to tabulate cases from the mail and the non-mail component. The mail component was not designed to estimate the total population.

Census Bureau's annual Company Organization Survey.

Data for the ASM are collected in all years except for years ending in 2 and 7, when the ASM data are collected as part of the Economic Census. Data on payroll, employment, industry, and geography for establishments in the non-mail stratum are obtained from administrative records.<sup>34</sup>

The ASM sample is designed to estimate unbiased national level estimates of a skewed population. For example, in the 2014 ASM panel, large establishments sampled with certainty account for approximately 72% of the total value of shipments in the 2012 Census of Manufactures; non-certainty establishments are sampled with probabilities from 0.05 to 1.00.<sup>35</sup> This sample design implies that the establishment counts in various size bins may not reflect those calculated from the LBD.

The ASM sample weights, which are inversely proportional to a shipments-based establishment size measure, could in principle be used to correct for the effects of the ASM sample design. However, the sample design implies that the weighted sum of shipments from the mail stratum only will not match published totals.<sup>36</sup>

Another important aspect of the sample design is that the composition of establishments changes over time and between sample selections. Any weighting procedure aiming at creating unbiased estimates of productivity dispersion should account for the fact that the sampling probabilities, and therefore the composition of the ASM, change every 5 years. In addition, sampling and non-mail stratum thresholds vary across years.

---

<sup>34</sup> Federal regulations require the Census Bureau to limit survey response burden.

<sup>35</sup> Source - ASM Methodology website, <https://www.census.gov/programs-surveys/asm/technical-documentation/methodology.html> (accessed September 16, 2020).

<sup>36</sup> As mentioned above, only the mail component together with the adjustment for the non-mail stratum yields unbiased estimates of the total population. See Davis, Haltiwanger and Schuh (1996) for more details.

## *B.2. Establishment Characteristics and the Probability of Selection into the ASM*

The ASM's sample design has important implications for our analysis. For example, the sum of the ASM sample weighted employment or sales might equal total employment or total sales. However, it is not clear that the ASM sample weights are appropriate for our analysis. This section is devoted to describing our weighting procedure.

To address the effects of the ASM's sample design, we construct propensity score weights using the Longitudinal Business Database (LBD). See Chow et al. (2021) and Jarmin and Miranda (2002) for more details about the LBD. The propensity score weights are constructed from a logistic regression in which we model the relationship between establishment characteristics and the probability that an establishment is selected into the ASM. We start by matching establishments in the ASM to LBD establishments by year and "LBD Number."<sup>37</sup> Our dependent variable is a dummy variable that equals one if the establishment is in both the ASM and the LBD for that year and zero if the establishment is only in the LBD. For establishments in the non-mail stratum, the dummy variable is set to 0.

The set of regressors includes dummy variables that classify each establishment based on its employment and payroll size class, whether the establishment is part of a multi-unit entity, the establishment's industry code, and the interaction between industry and employment size effects. Including industry-size interactions allows us to estimate industry-specific size distributions. These variables are obvious candidates for our logistic regressions because the probability of selection into the ASM sample and the cutoff for the non-mail stratum in the ASM vary by industry and size.

When determining weights, we define industries at the 3-digit NAICS level because the

---

<sup>37</sup> The LBD Number is an establishment identifier that is consistently defined across both datasets. Although linking the datasets by LBD Number is straightforward, a small percentage of establishment-year observations do not match due to timing issues between the ASM and the LBD.

interaction of size indicators and more narrowly defined industry codes leads to empty cells in smaller industries. Empty-size bins imply that the size distribution cannot be estimated in these industries.<sup>38</sup> When the size distribution cannot be estimated for an industry, propensity scores cannot be calculated because maximum-likelihood estimates of the size effects do not exist. Empty cells can, in principle, be avoided by collapsing size bins, combining similar narrowly defined industries, or allowing bin definitions to vary across industries. We experimented with the number and definition of the size bins and the level of industry aggregation and found that using 3-digit NAICS industry codes together with 4 size bins allows us to estimate the size distribution in every industry and year. Allowing for more heterogeneity by using either industry-specific size bins or more narrowly defined industries leads to feasibility problems with the logistic regression.

We defined the size bins so that the resulting distribution allows the lowest size bins to vary over time. That is, in every year and every industry, the 50<sup>th</sup> percentile of establishments with fewer than 50 employees is used to define bins 1 and 2. For larger establishments, the following bins are defined: 50–99, 100–199, and 200+.<sup>39</sup> There are 21 3-digit NAICS industries in the 2002 classification system, which results in 105 industry specific size distributions. We include a continuous size measure to allow the weights to vary within these cells. This is necessary to account for possible within-cell compositional changes. Adding 5 payroll classes and 2 groups related to multi-unit status increases the number of cells to 113.<sup>40</sup>

The 2002 change in the industry classification system resulted in missing NAICS-2002 codes for a nontrivial number of establishments in the LBD between 1997 and 2001. For example, the NAICS code is missing if an establishment exited prior to 2002. For these

---

<sup>38</sup> The size distribution cannot be estimated if all establishments are in the same size bin.

<sup>39</sup> The payroll size classes are 0–200, 201–500, 501–1000, 1001–5000, 5001+.

<sup>40</sup> If we were to use 4-digit industry, the number of cells would increase significantly. There are 86 4-digit NAICS industries implying 86 different size distributions and 430 industry-size cells. Such an increase in the number of cells yields empty size bins in several industries.

observations, we used imputed NAICS codes.<sup>41</sup> From 2002 on, NAICS codes are available for all establishments in the LBD.

Our inverse propensity score weights generate employment counts that do a good job of matching the trends and cyclical variation in BLS manufacturing employment, but they do not match BLS levels.

### *B.3 Comparison of Hours Measures*

In this study, we use hours data from ASM, augmented with data from the CPS. However, for official estimates of productivity growth, BLS uses the CES as its primary source of hours data. Although the CES and ASM are establishment surveys, the two surveys differ in what hours data they collect and how they collect it. The best information on these differences comes from studies completed in the early 2000s (Goldenberg and Willimack, 2003; and Fisher et al., 2001). These studies do a nice job of summarizing the differences between the two surveys and how those differences affect estimates of hours worked. In this appendix, we summarize that research and discuss the implications for comparing our estimates to published BLS estimates.

There are some general differences between the two surveys that are worth noting. First, the ASM is an annual survey, whereas the CES is conducted monthly. As a result, the reference periods of the two surveys differ. The reference period for the CES is the pay period that includes the 12<sup>th</sup> of the month. The CES collects data on the total number of employees, hours for all employees since 2006, the number of production workers, production worker payroll and production worker hours.

In contrast, the ASM has different reference periods for different data elements. For production worker employment, the ASM reference period is the pay period that includes the

---

<sup>41</sup> NAICS codes are imputed using a method described in Fort (2013).

12<sup>th</sup> of the month in the months of March, May, August, and November. These quarterly reports are then averaged into an annual number. The ASM collects employment data for other employees only for the pay period that includes March 12<sup>th</sup>. The implicit assumption is that nonproduction worker employment does not vary much over the year. Total employment is not collected directly, but rather is equal to the sum of nonproduction worker employment in March and the annual average of quarterly production worker employment.

Annual total employment in the two surveys can differ if there are seasonal patterns in production worker employment that are missed in the ASM's quarterly reports or if there is a seasonal pattern to nonproduction worker employment. We examined this issue using monthly CES data. Specifically, we calculated the average employment for each quarter using CES data, and then calculated the ratio of average quarterly employment to CES employment in the ASM reference months (March, May, August, and November). The ratios were very close to one, showing that estimates of average annual employment are the same whether we use four quarterly reports or 12 monthly reports.

There are greater differences in the hours data collected in the two surveys. First, the two surveys use different concepts. The ASM asks employers to report hours *worked*, whereas the CES collects hours *paid*. The main difference is that the CES hours data include holidays, annual leave, and sick leave that were paid but not worked. Thus, we would expect total annual hours reported in the ASM to exceed total annual hours in the CES. For productivity measurement, hours worked is the correct concept, which is why BLS adjusts the CES data using hours-worked-to-hours-paid ratios from the NCS.

The two surveys also differ in how they ask respondents to report hours. The ASM asks respondents to report total annual production worker hours. The CES asks respondents to report total production workers for the pay period that includes the 12<sup>th</sup> of the month. The hours reports are converted to a weekly number using conversion factors that vary with the number of

workdays in the month. Apart from the difference in concept, these two approaches to collecting hours data could result in different estimates of total annual hours. Research by Frazis and Stewart (2004) has shown that people work longer hours during the week that includes the 12<sup>th</sup> of the month.<sup>42</sup> This would lead to annual hours in the CES being higher than in the ASM and would offset some of the difference due to the difference in concept. Neither survey collects hours data for nonproduction workers. As noted in the text, nonproduction worker hours are estimated using data from the CPS.

---

<sup>42</sup> Their research examined the accuracy of CPS hours reports by comparing the CPS hours data to hours data from the American Time Use Survey (ATUS). Subsequent research by Eldridge, Pabilonia, and Stewart (2019) found differences in some years, but not in others.
